

TITLE OF THE INVENTION

DEMULTIPLEXING A STATISTICALLY MULTIPLEXED MPEG TRANSPORT STREAM INTO CBR SINGLE PROGRAM TRANSPORT STREAMS

5

BACKGROUND OF THE INVENTION

The present invention relates to video compression, and more particularly to a simple method for demultiplexing a statistically multiplexed MPEG transport stream (MPTS) into constant bit rate (CBR) single program transport streams (SPTSs) without making any changes to the video elementary streams.

15
SUB A' 1
The video elementary streams in the MPTS are all typically encoded with a variable bit rate (VBR). Only if the constant bit rate is too low does it become impossible to demultiplex a single stream from the MPTS without modifying the video elementary stream. Obviously this is the case if the average bit rate of the VBR stream is greater than the constant bit rate of the CBR stream. Even in this case, it is usually possible to ameliorate the potential visual artifacts by replacing B-type pictures with null B-type pictures.

20 Prior efforts that achieve the demultiplexing of a statistically multiplexed MPTS into multiple CBR SPTSs do so by modifying (transcoding) the video streams — while more general, it is a much more compute intensive process and can negatively impact the quality of the resultant video. Examples of such products are the CherryPicker 7000
25 video re-multiplexer from Terayon Communication Systems located in Santa Clara, California, United States of America and possibly the PS5030

Multiplexer Module from PixStream Incorporated located in Waterloo,
Ontario, Canada.

In a statistically multiplexed MPTS, video streams are encoded as
VBR with a wide distribution of bit rates per picture. The transport
5 packets (TPs) for a given video stream arrive in almost as bursty a pattern,
though there is some smoothing. What is desired is to fit a complete SPTS
with VBR video and CBR audio within a CBR network connection without
recoding or modifying the video in any way.

10 BRIEF SUMMARY OF THE INVENTION

Accordingly the present invention provides a simple method for
demultiplexing a statistically multiplexed MPEG transport stream into
CBR single program transport streams without recoding or modifying the
video in any way. The method starts sending a picture at a fixed interval,
15 on the order of tens or hundreds of milliseconds, before it is to be decoded
or as soon thereafter as possible. A separate logical smoothing buffer is
used for each variable bit rate single program transport stream. When the
decode time arrives the picture is transferred from the smoothing buffer for
decoding. In the event there is buffer overflow, B-type frames are replaced
20 with null B-type frames, which has the effect of a freeze frame by
repeating the prior decoded picture, until the overflow condition ceases.

The objects, advantages and other novel features of the present
invention are apparent from the following detailed description when read
in conjunction with the appended claims and attached drawing.

BRIEF DESCRIPTION OF THE SEVERAL VIEWS OF THE DRAWING

Fig. 1 is an illustrative view of a statistically multiplexed MPEG Transport Stream having variable bit rate single program transport streams.

Fig. 2 is an illustrative view of the relationship between the input variable bit rate single program transport stream and the constant bit rate single program transport stream produced using a smoothing buffer according to the present invention.

Fig. 3 is an illustrative timing view showing the loading of the pictures into the smoothing buffer at the constant bit rate starting at a fixed time prior to the decode time, or as soon as possible thereafter, according to the present invention.

DETAILED DESCRIPTION OF THE INVENTION

Referring now to Fig. 1 a statistically multiplexed MPEG Transport Stream (MPTS) having a plurality of programs of variable bit rates multiplexed together is illustrated. The shadowed packets represent a single program transport stream, Program 1, the packets of which all are a part of the same program. As shown between PCR 0 ms and PCR 1.8048 ms Program 1 has one-third of the packets that are interleaved with those of other programs at an MPTS stream rate of 10 Mbs, i.e., 0.1504 ms per MTS packet. The bit rate for Program 1 over that interval is 3.33333 Mbs. Between the next two PCRs at 1.8048 ms and 2.1056 ms are only two Program 1 packets with no interleaved packets so the Program 1 bit rate is

that of the MTS stream, i.e., 10 Mbs. The different bit rates for Program 1 depend upon, for example, image complexity and the type of MPEG frame — I, P or B.

The SPTS(VBR) is separated from the MTS based upon the packet PIDs, and is input to a logical smoothing buffer at the desired constant bit rate to produce an SPTS having a Constant Bit Rate (CBR). The SPTS (CBR) may then be decoded at the time indicated by the decode time stamp (DTS) for each frame to recover the original images in the video stream.

As shown in Fig. 2 for an SPTS (VBR) that has an Average Bit Rate (ABR) less than the desired CBR, there are times when the SPTS (VBR) exceeds the CBR. In the absence of the present invention this causes those pictures not to be decoded, resulting in repeated frames since the prior frame is repeated if the next frame is not decoded. The still frame remains until the next complete image or frame is available for the decoder at the time indicated by the associated decode time stamp (DTS). To prevent this undesired anomaly, the solution according to the present invention is to start loading the buffer early with the packets for a frame so that when decode time comes the full data for the frame is available for decoding, as illustrated in Fig. 3 and described in more detail below.

Buf_n represents the smoothing buffer for variable bit rate (VBR) video elementary stream n within a statistically multiplexed MPEG transport stream (MPTS). The variable $td_n(j)$ is a decode time for the j 'th

Sub A2
a.u.c.

picture of the video elementary stream \underline{n} in a system target decoder.

Decode time is measured in seconds and is with respect to a system clock

PCR for the program containing elementary stream \underline{n} . The variable $t_n^i(j)$ is

a time at which the i 'th transport stream (TS) packet of the j 'th picture of

5 elementary stream \underline{n} enters the smoothing buffer Buf_n . Again time is

measured in seconds and is with respect to the system clock for the

program containing elementary stream \underline{n} . R_n is based on the desired bit

rate shown in Fig. 2 — it is the desired bit rate less the bit rate of the

packets in the SPTS not carrying video. R_n is a constant rate at which the

10 TS packets with the video elementary stream \underline{n} enter the smoothing buffer

Buf_n . The rate is given in units of bits per second. Finally δ_n is the earliest

time before the decode time that a video elementary stream TS packet can

enter the smoothing buffer Buf_n . Again time is given in seconds.

The buffer size is given by $|\text{Buf}_n| = R_n \delta_n$. TS packets containing

15 video elementary stream \underline{n} enter Buf_n as early as possible subject to the

following constraints:

1. The rate at which the packets can enter Buf_n is limited by R_n .

2. For any picture j of video elementary stream \underline{n} and for all TS packets
containing picture j , $t_n^i(j) + \delta_n \geq td_n(j)$.

20 3. At time $td_n(j)$ all of the packets $t_n^i(j)$ are removed.

4. If the buffer Buf_n is full, i.e., contains $R_n \delta_n$ bits, then no new packets
can enter.

The buffer model is satisfied if the buffer Buf_n never overflows or underflows. An overflow or underflow occurs when for any picture j of video elementary stream n and any TS packet containing picture j ,
 $t_n^i(j) > td_n(j)$.

In the event of overflow a B-type frame is replaced by a null B-type frame until the overflow ceases, which has the effect of repeating the prior video frame by the decoder, as described in co-pending U.S. Patent Application No. 09/113,669 entitled "Readjustment of Bit Rates When Switching Between Compressed Video Streams" by Douglas C. Stevens et al.

The above is illustrated in Fig. 3 where a series of frames of variable bit rates is shown. At time δ before the DTS for frame 1, frame 1 is loaded into the buffer. The buffer may be thought of as having a plurality of equal capacity slots between consecutive DTS times. Since frame 1 has fewer bits than the capacity of one slot, there is a gap before frame 2 is loaded into the buffer, again at time δ before the DTS for frame 2. Likewise frame 3 is loaded at time δ before DTS_3 . Frame 3 has more bits than fit into one slot, so that frame 4 is loaded into the buffer as soon as possible thereafter. Then frame 5 is loaded into the buffer as soon as possible. The end of frame 5 almost exceeds the DTS time for frame 5 and the buffer is in danger of overflowing. However the next few frames 6, 7 and 8 each have fewer bits than one slot so that the capacity of the buffer is alleviated.

Thus the present invention provides for demultiplexing a

- statistically multiplexed MPEG transport stream into a constant bit rate single program transport stream using a smoothing buffer with the video pictures in the stream being loaded into the smoothing buffer at the desired constant bit rate as early as possible up to a fixed time interval
- 5 before the pictures need to be decoded.
